

**First Project -
Airport Security Queues**

CS166 - Modeling and Analysis of Complex Systems

February 2, 2025

1 Introduction

Efficiently managing queues in airport security screening is a critical operational challenge. Airports must balance security manpower with incoming passengers while optimizing smooth screening to minimize waiting times. This project aims to investigate how different queue configurations impact waiting times, average queue lengths, and overall efficiency. Specifically, it will make a recommendation on the amount of airport security to ensure smooth operation. To find the best security station set-up, we will implement a simulation that models the airport security queueing system, analyze its performance under different conditions, and compare empirical results with theoretical predictions from queueing theory.

2 Theoretical Analysis

2.1 Model Description

Models are simplified representations of real-world systems. They preserve key relationships and interactions between essential components while making assumptions and simplifications to facilitate analysis and manipulation. The analysis of airport security stations' configuration relies on the queueing theory, which provides a mathematical framework to analyze waiting lines with varied set-ups.

The security screening queue system involves travelers arriving at random intervals, joining the shortest available queue, and undergoing screening. Each security station serves one traveler at a time, and follows the first-come-first-out (FIFO) discipline. Additionally, some of the travelers require further screening. There is only one senior officer that can perform additional screening and everyone in the queue will wait until it finishes.

The parameters include arrival rate $\lambda = 10$ arrivals per minute, service rates $\mu = 30$ seconds per traveler, and $\mu_2 = 2$ minutes per traveler (for normal screening and additional screening). The airport opens all day everyday, thus there will not be breaks between services. Also, we assume the system has an infinite buffer, meaning the queues can grow infinitely long and the travelers will always wait until they are served.

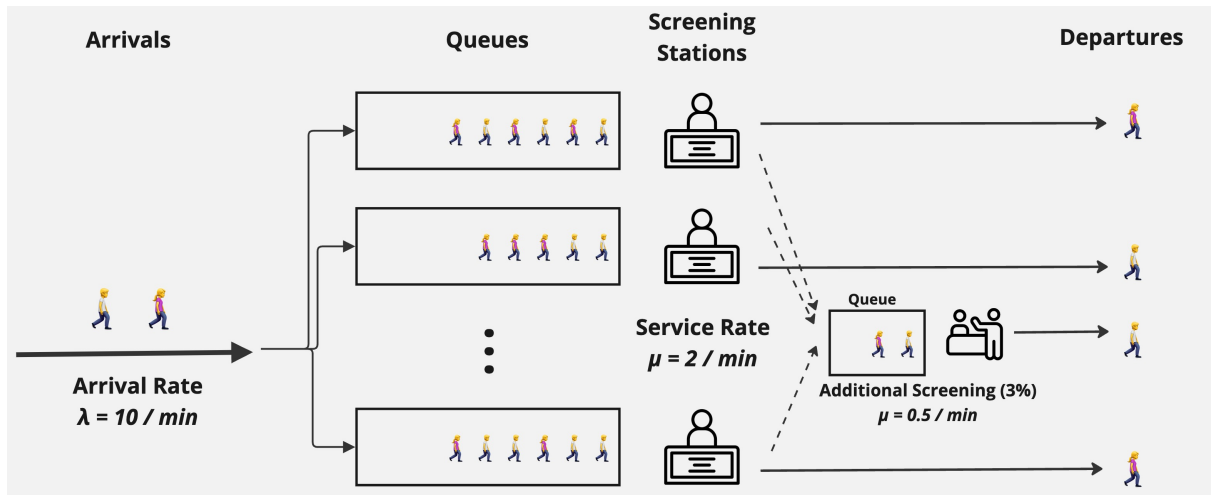

Figure 1: Conceptual diagram of the airport security screening queue system.(self-made)

2.2 Mathematical Framework

2.2.1 The Arrivals

In the queueing theory, the travelers' arrival follows a Poisson process, meaning the inter-arrival times between travelers follow an exponential distribution. This brings about two important assumptions: each arrival is independent from another and the average rate λ does not change during the simulation. This makes the system memoryless, which means knowing when the last customer arrived provides no information about when the next customer will arrive.

The arrival rate (λ) is

$$\lambda = 10 \text{ travelers per minute,}$$

which corresponds to the scale parameter of the exponential distribution being $\beta = \frac{1}{\lambda} = \frac{1}{10}$. The probability density function for travelers arrival is:

$$f(x; \lambda) = \begin{cases} \lambda e^{-\lambda x}, & x \geq 0 \\ 0, & x < 0 \end{cases}$$

Some properties of the exponential distribution include the mean and the expected value of the inter-arrival time being $\frac{1}{\lambda} = \frac{1}{10}$ minutes, and the variance of $\frac{1}{\lambda^2}$ minutes.

2.2.2 The Queues

After the travelers arrive at the airport, they join the shortest queue where they start the wait. There are multiple parallel security screening queues, each of which is an **M/G/1** queue. The **M** refers to *Markov Chain*, which is the assumption that arrivals are exponentially distributed and therefore memoryless. The **G** means *General*. In this case, we assume that the service time per traveler follows a Truncated Normal distribution. The final **1** means there is one service station per queue.

Suppose there are n security queues, the arrival rate for each queue is:

$$\lambda_1 = \frac{10}{n} \text{ travelers per minute.}$$

Each security screening station processes travelers one at a time, with a service time that follows a Truncated Normal distribution with a mean of 30 seconds ($\mu_1 = 30$) and a standard deviation of 10 seconds ($\sigma_1 = 10$). The truncated normal distribution in this case is cut off at 0 to avoid negative values. The probability density function is given by:

$$f(x; \mu_1, \sigma_1, a = 0, b = \infty) = \begin{cases} \frac{\frac{1}{\sigma_1} \phi\left(\frac{x - \mu_1}{\sigma_1}\right)}{\Phi\left(\frac{b - \mu_1}{\sigma_1}\right) - \Phi\left(\frac{a - \mu_1}{\sigma_1}\right)}, & a \leq x \leq b, \\ 0, & \text{otherwise.} \end{cases}$$

where $\phi(\cdot)$ is the probability density function of the standard normal distribution and $\Phi(\cdot)$ is its cumulative distribution function.

Since the mean service time is 30 seconds (or 0.5 minutes) per traveler, the service rate (μ) is:

$$\mu_1 = \frac{1}{0.5} = 2 \text{ travelers per minute}$$

The utilization rate of each of the general queues (ρ_1) is given by:

$$\rho = \frac{\lambda_1}{\mu_1} = \frac{10}{n} \times \frac{1}{2} = \frac{5}{n}$$

This ratio helps determine whether queues are stable; a system is stable only if $\rho < 1$, meaning the number of service stations must satisfy $n > 5$. However, the stability of the system can be influenced by the additional screening process, too.

There is a 3% probability that a traveler will require additional screening. A senior officer will move around the general queues for those in need, and the process follows FIFO discipline. It can also be seen as an individual M/G/1 queue for computational clarity (and it does have properties of a queue). However, when the senior officer performs the additional screening, everyone in the queue from which the traveler originally comes will wait until they finish. Thus, this queue's behavior can influence the general queues' performance significantly.

The arrival rate to this queue is:

$$\lambda_2 = 0.03 \times 10 = 0.3 \text{ travelers per minute}$$

The service time follows a Truncated Normal distribution with a mean of 2 minutes ($\mu_2 = 2$) and a standard deviation of 2 minutes ($\sigma_2 = 2$). The corresponding service rate is:

$$\mu_2 = \frac{1}{2} = 0.5 \text{ travelers per minute}$$

Since there is only one queue (the senior security officer) handling additional screenings, the utilization rate (ρ_2) is:

$$\rho_2 = \frac{\lambda_2}{\mu_2} = \frac{0.3}{0.5} = 0.6$$

This utilization rate indicates that the additional screening queue is expected to be busy 60% of the time but should remain stable as long as $\rho_2 < 1$.

2.2.3 Measuring performance

We will simulate the model in the next section. By comparing theoretical results with empirical simulations, we aim to validate the model's accuracy and determine the optimal number of security stations required for stable passenger flow, balancing efficiency with resource allocation.

3 Empirical Analysis

3.1 Simulation Design and Implementation

3.1.1 Testing Code

The code for testing was first crafted, which includes several `print()` functions that show each step the system takes. This is to ensure that there is a working code available for simulation and that the code functions exactly how we want it to. The code is shown in Appendix A, following 4 test cases of scenarios in Appendix B.

3.1.2 Simulation Code

In Appendix C, all the *print()* functions are removed in the simulation code as the queueing system will be run many times, and we have already made sure that there is a functioning code capturing the dynamics of the system. Except for the *print()* functions, the testing code and simulation code are identical. The library *tqdm()* is implemented to track the progress of the simulation.

3.1.3 Simulation of A Day

The first simulation observes the dynamics of the airport security queueing system in a day. It aims to identify the optimal number of queues for reaching the equilibrium state by setting different numbers of queues in each simulation. It tracks the fluctuation of individual queue length and the waiting time of each traveler in a day. The code is in Appendix D.

3.1.4 Simulation of Key Performance Indicators

After identifying two possible optimal queue lengths, the second simulation measures the performance indicators: average queue length in a day, maximum queue length in a day, and average waiting time in queue. The code is in Appendix E.

3.2 Simulation Results and Discussion

3.2.1 Simulation of A Day

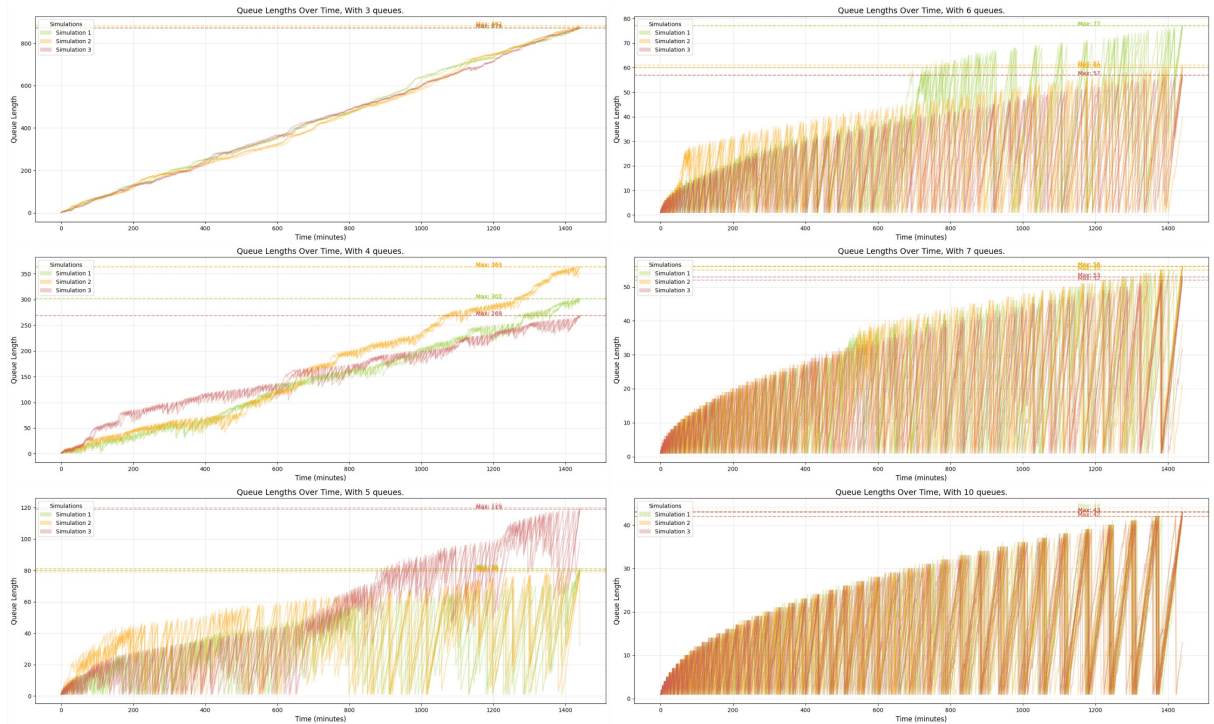

Figure 2: Queue length over time in a day. Please note that the y axis' higher limits are different for each graph, the y limits are adjusted this way to demonstrate the fluctuations within each system closely. The systems with fewer queues have higher maximum queue lengths in their oscillation.

As we calculated above, the utilization rate of the general screening queues is

$$\rho = \frac{\lambda_1}{\mu 1} = \frac{5}{n},$$

where n is the number of queues. A stable system requires $\rho < 1$, meaning that $n > 5$ is necessary. Figure 2 shows the queue length over time under three unstable settings (with 3, 4, and 5 queues) on the right and three stable settings (6, 7, and 10 queues) on the left. Figure 3 shows the wait time for each traveler with the same setting, the traveler number represents travelers' order to enter the airport system.

With 3 and 4 queues, we can see that the queue length grew linearly with the incoming travelers and the service was barely processing anyone out. This means the system was not able to reach an equilibrium and the queue length would grow indefinitely. The simulation with 4 queues had more oscillation because the queues were able to process some travelers but the arrivals were still overwhelming for the system.

With 5 queues, the oscillation increased largely in magnitude and the queue length went back to 0 from time to time. The 3 simulations (each with 5 queues) also has different traces. This shows that when utilization(ρ) is exactly 1, the system can sometimes be balanced (back to 0 queue length) but it is vulnerable to randomness given the arrival and service time are probabilistic and the 3% chance of additional screening.

With 6, 7, and 10 queues, the utilization rate is less than 1, meaning that the system is able to reach equilibrium. The systems' ability to balance arrival and service rates was reflected in their oscillation which always goes down to zero in every cycle. With 6 and 7 queues, some events significantly increased the queue length. This is due to the possibility of going into a long additional screening process. The system can function stably (without extremely long waiting times that significantly increase the queue length) and predictably when the number of queues reaches 10. When the possibility for additional screening was removed, the system was able to reach a stable state with 6 queues (see Figure 3).

Figure 3: Wait time for each traveler in a day without additional screening.

The wait time plots (Figure 4) behave similarly as the queue length plots. With 3 to 5 queues, the queues were not balanced and the wait time eventually grew indefinitely. With 6 to 10 queues, the wait times have oscillations but always fall back to 0 in each cycle, showing stably functioning systems.

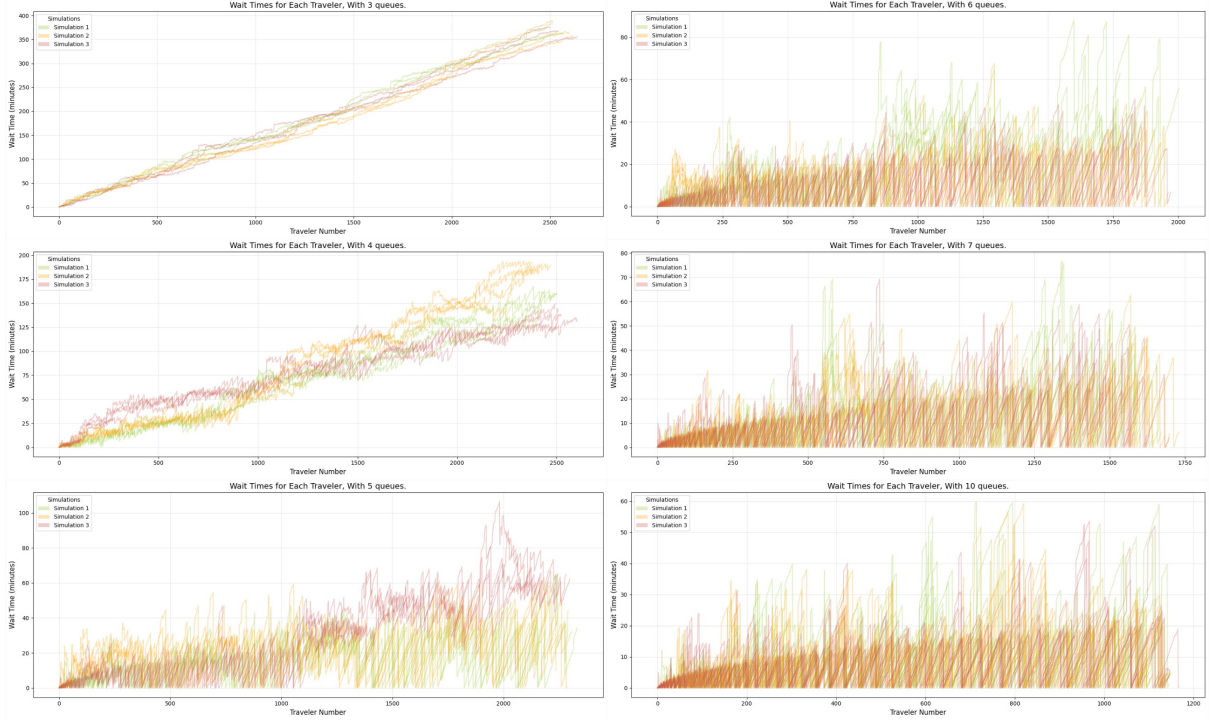

Figure 4: Wait time for each traveler in a day. Please note that the y axis' higher limits are different for each graph, y limits are adjusted this way to demonstrate the fluctuations within each system closely. The systems with fewer queues have higher maximum waiting times in their oscillation.

Based on the result of the simulation, I selected the queueing systems of 7 queues and 10 queues as possible choices for recommendation. I chose 7 queues because even though the system with 6 queues does reach equilibrium empirically and has $\rho < 1$ utilization rate theoretically, it behaves relatively unstably with some events significantly increasing the queue length. With 7 queues, the system was able to digest the extreme events better and faster. I chose 10 queues too because for 7 to 9 queues (for code to generate them, see Appendix D), there were still a few disturbances in the queueing system while for 10, the system digested the travelers stably without significant disturbance. This is shown in Figure 4, there are still very long individual wait times for the 10 queue systems but are not causing fluctuations of queue lengths in Figure 2.

3.2.2 Simulation of Key Performance Indicators

Figure 5: Performance Indicators for Queueing System with 7 Queues

For the queueing system with 7 queues, the histogram for the average queue length shows a right-skewed distribution, with the mode near 20 (people). The mean average queue length is 20.24, and the 95% confidence interval (CI) is [16.21, 24.27], indicating that the true average queue length is 95% likely to fall within this range. For the maximum queue length, the histogram similarly shows a right-skewed pattern, with an expected value (mean) of 56.09 and a 95% CI of [45.84, 66.33]. Lastly, the histogram for the average wait time reveals a mean of 12.48 minutes, and a 95% CI of [8.50, 16.45]. All three distributions are slightly skewed to the right, which aligns with the probabilistic nature of the arrivals and the memoryless property of the Poisson process influencing the queue system.

Little's Law is a theorem in queueing theory that states the average number of customers in a system (L) is equal to the product of the average arrival rate (λ) and the average time a customer spends in the system (W), expressed as

$$L = \lambda W,$$

disregarding the arrival and service distribution. For this system, where the arrival rate λ is $10/7 \approx 1.43$ travelers per minute and the average waiting time W is 12.48 minutes, the theoretical average queue length L is $1.43 \times 12.48 \approx 17.83$. This value is lower than the empirical mean of $L = 20.24$. The differences can be caused by random delays caused by variability in arrival and service times, and the impact of the senior officer handling additional screenings that require longer service time.

Figure 6: Performance Indicators for Queueing System with 10 Queues

The performance of the queueing system with 10 queues exhibits better efficiency. The histogram for the average queue length shows a tighter concentrated distribution around a mean of 15.53. The 95% CI of [14.29, 16.78] indicates that we have narrowed down the range for the true population mean and increased the system's predictability, which aligns with the observation that 10 queue systems are more stable. The maximum queue length has a mean of 43.44, a 95% CI of [40.08, 46.80]. The average waiting time is also reduced, with a mean of 9.6 minutes and a 95% CI of [6.95, 12.26]. These metrics indicate that the system with 10 queues is better balanced and operates with minimal fluctuations.

Applying Little's Law to this system, which has an arrival rate λ of $10/10 = 1$ traveler per minute and an average waiting time W of 9.60 minutes, the theoretical queue length L is $1.0 \times 9.60 = 9.60$. This theoretical value is also lower than the empirical mean of $L = 15.53$ due to the same factors affecting the 7 queue system: random variation in arrivals and service times, and the delays caused by the additional screening process.

4 Recommendations

With theoretical and empirical analyses, this report has explored how queue configurations affect the efficiency and stability of an airport security screening system. Theoretical calculations found out that at least 5 queues are required to maintain equilibrium, and empirical simulations confirmed the system's ability to reach a relatively stable equilibrium state under varying queue setups. However, while increasing the number of queues enhances efficiency by reducing wait times and queue lengths, resource allocation should also be considered.

Based on the findings, the recommendation is to implement 7 queues, which provide a balanced trade-off between efficiency and resource constraints. The empirical analysis showed that this configuration maintains a fairly stable system, with an average waiting time of 12.48 minutes and a maximum queue length of about 56—both of which are reasonable given that most travelers have buffer time for check-in and security screening. Although the 10-queue system showcases slightly better performance, the additional costs may not justify the marginal gains.
